19. ABSTRACT (Continue on reverse if necessary and identify by block number) Computer calculations were performed to determine the maximum allowable valve opening times for producing sharply defined shocks of certain specifications ranging from 13.8 kPa to 241 kPa in the proposed Large Blast/Thermal Simulator for the U.S. Army Ballistic Research Laboratory. The maximum allowable valve opening times range from 63 milliseconds for the highest shock overpressure to 21 milliseconds for the lowest shock overpressure in the specified overpressure range.

1. INTRODUCTION

The Ballistic Research Laboratory (BRL) of the U.S. Army is designing a Large Blast/Thermal Simulator (LB/TS), which is a proposed facility for creating pressure and thermal transients like those that occur near nuclear explosions.⁽¹⁾ The LB/TS is basically a large shock tube with area changes along its length. Unlike a conventional shock tube, which uses rupture diaphragms to separate the high pressure driver region from the low pressure driven region, it is desirable to utilize fast-opening valves in the LB/TS for wave shaping purposes as well as operational efficiency. However, with real valves, a finite opening time results in a compression wave with a finite rise time. The question then arises as to whether the compression wave will steepen to an adequate shock profile within the specified wave propagation distance, to simulate the desired blast wave. In support of this design effort, the Mathematical Analysis Unit at the Idaho National Engineering Laboratory (INEL) has done calculations to determine the maximum throat valve opening times allowable for the creation of certain shock waves in the LB/TS test section. Calculations were done for 9 specific cases specified by the BRL, representing 9 different initial conditions in the shock tube driver. All the calculations were done with the BRL-Q1D computer code⁽²⁾. This report summarizes the results of the valve opening calculations.

2. CALCULATIONS

For the present studies, the LB/TS was represented by the shock tube shown in Figure 1 and described in Table 1. We are interested in the initial magnitude and rise time (not the later decay) of the shock at the test section 103.5 meters from the valve. The objective of the present study is to determine how fast the valve must open to allow the overpressure to rise from 5% to 95% of the plateau value in 0.5 milliseconds or less. We are not concerned with reflections from the end of the shock tube, which arrive too late to affect the shock front of interest. This allows us to model a shock tube substantially shorter than the real LB/TS, thereby saving some computer costs.

Calculations were done for the 9 cases listed in Table 2, representing different initial temperature and pressure conditions in the driver. Case 9 was different from the other 8 in that the shock tube geometry was a little different (see Table 1) and the valve was opened to a maximum of 43.75% instead of 100%.

The valve was represented as a parabolic constriction with a total length of 2 meters, located in the middle of the throat. The valve opening was represented as a linear function of time, from 0.1% open at time zero to 100% open (43.75% open for case 9) at the specified valve opening time. In addition to these calculations with the valve opening gradually, a reference calculation was done with the valve opened instantaneously for each case, to insure adequate resolution of the shock wave structure with the mesh used and, in some instances, to compare certain features of the wave structures.

Table 1: Shock Tube Geometry

6	39.5	1.228	68.9	74.0	0.050
7	19.5	1.094	34.5	39.6	0.035
8	7.0	1.040	13.8	15.57	0.021
9	8.9	1.040	13.8	4.634	0.026

The calculations were done on INEL's CRAY X/MP-24 computer. Two minor modifications were made to the BRL-Q1D code: the sizes of the grid-dependent arrays were increased, and the plot and print output of time-dependent arrays was not started until the shock reached the first measurement station. For cases 8 and 9, the code was further modified by overlaying some large arrays, to decrease computer memory requirements and thereby improve computer access and turn-around time.

The BRL-Q1D code includes two options for the numerical method: the Beam-Warming and the MacCormack methods. For these calculations, the Beam-Warming method was used, with the BRL-recommended values of 1.0 for the Courant number and 0.04 for the smoothing coefficient. Preliminary estimates suggested that 10000 grid points would be adequate for these calculations, and this number was used successfully for cases 1-6. More grid points were required for cases 7-9.

3. RESULTS

The results for case 1 are given here in some detail; results for the other cases are given in much less detail, only as is necessary to describe significant differences from the results for case 1.

Figures 2-15 indicate the temporal and spatial dependence of some important variables calculated by the BRL-Q1D code for case 1 with the valve instantaneously opened 100%. In Figures 2-13, the horizontal axis is the normalized distance along the length of the shock tube. The actual total length corresponding to the normalized length of 1 is indicated by the value of L_{ref} (200 meters for case 1) printed at the top left corner of the page. The profile of the shock tube is indicated above the data plot, on the same horizontal scale as the data plot. The dependent variables plotted on the vertical scale in Figures 2-13 are also normalized to reference values as described in the BRL-Q1D code documentation.⁽²⁾ The number printed just above the right end of each curve in Figures 2-13 is the time corresponding to that curve, in seconds. In Figures 10-13, the horizontal scale is expanded enough so that the individual points of the spatial grid are discernible, indicated by the vertical lines in the shock tube profile drawn above the graph proper. These graphs with high spatial resolution clearly indicate the spatial spread of the computed shock front, which is useful in evaluating the adequacy of the numerical method.

Figures 14 and 15 are graphs of overpressure (solid line) and dynamic pressure (dashed line) versus time, at the test location specified by the value listed for X-sta at the top of the page. The indicated distance of 97.5 meters from the beginning of the expansion tube corresponds to the required 103.5 meters from the center of the valve.

The data of most immediate interest is the overpressure versus time data indicated by the solid curves in Figures 14 and 15. This overpressure rises abruptly -- in a fraction of a millisecond -- when the shock arrives at the test location. At the top of this step is a small overshoot that is an artifact of the numerical procedures and is not indicative of a real phenomenon; the actual overpressure step is better indicated by extrapolating the almost-horizontal curve from the right of the step into the region of the step itself. This extrapolation procedure was used to estimate the overpressure step in all the studies reported here.

After the initial shock transient, the overpressure approaches a constant value, a plateau value, which is different for each of the 9 cases. This plateau value is used as the reference overpressure for each case.

Figures 16-29 illustrate the effect of the valve opening gradually instead of instantaneously. These figures represent a valve opening time of 65 milliseconds, which is close to the maximum allowable valve opening time for case 1. The major effect is to decrease the magnitude of the overpressure step and to increase the slope of the overpressure versus time curve after the initial shock. The rise time for the initial step is not noticeably changed by the gradual opening of the valve. Since the slope of the overpressure versus time curve after the initial shock is practically zero on a millisecond time scale, the acceptance criterion is essentially equivalent to the requirement that the magnitude of the overpressure step with the valve opened gradually be at least 95% of the reference overpressure. Thus, the procedure for estimating the maximum allowable valve opening time was to try different opening times and check whether the shock overpressure step was at least 95% of the reference value. (Of course the shock rise time was also checked for each run, to be sure that it was less than 0.5 ms.)

This case 1 description is representative of the results for cases 1-5. Case 6 and 7 gave results similar to those described for case 1, except that the overpressure decreased slightly instead of increasing after the initial shock for the calculations in which the valve was opened instantaneously. This difference was not important in estimating the maximum acceptable valve opening time.

Cases 8 and 9 gave qualitatively different results, as indicated in Figures 30-39 for case 8 with the valve instantaneously opened. In these cases, the initial shock was followed after a few milliseconds by a second shock that raised the overpressure to a value substantially higher than that of the first shock. The timing and magnitude of the second shock depend on the details of the geometry in the throat region of the shock tube. Figures 40-93 show some detailed plots for case 8 with the valve instantaneously opened, and Figure 94 shows an x-t plot for this case. The second shock moves a little faster than the first shock, but does not quite overtake the first shock in the 103.5 meter travel distance to the test station. It appeared that moving the valve closer to the end of the throat would decrease the initial delay between the first and second shocks and perhaps allow the second shock to overtake and merge with the first shock before they reached the test location. This change in the valve location was tried and found effective for this particular problem; unfortunately, this created another shock even later, so that the overall effect was not significantly changed.

The general conclusion drawn from this examination of case 8 is that the details of the shock tube geometry near the valve can cause irregular behavior of the overpressure versus time plot for the shock front, more complicated than the simple step followed by an almost flat region. In fact, this same irregular behavior occurs in all cases (note Figure 3), but in the higher pressure cases the irregular structure is merged into one simple shock before the shock reaches the measurement station.

Of course the simple shock tube geometry assumed here and the one-dimensional fluid flow calculation used here may not accurately represent the actual shock tube valve, throat, and nozzle behavior; nevertheless, it would not be surprising if phenomena qualitatively similar to the double shock behavior calculated for case 8 actually occurred in the real LB/TS. The question of immediate importance here is whether the model is realistic or informative enough to be useful, and whether (and how) to proceed with the studies of acceptable valve opening times for cases 8 and 9. The BRL personnel consulted⁽³⁾ on this matter suggested proceeding with the calculations, with the understanding that the results might not be taken at face value. Thus, the results presented here for cases 8 and 9 should be regarded as plausible but perhaps not very accurate estimates of the actual shock tube behavior. These results are a little sketchy, but more detailed studies did not seem warranted in view of the high cost and limited validity of computer calculations for the low-pressure cases like cases 8 and 9.

Overpressure versus time plots for cases 8 and 9 are shown in Figure 38 and Figures 95-100. The overpressure step associated with the first shock front appears to vary in a consistent manner with valve opening time, if the valve is opened gradually instead of instantaneously, and the results obtained from considering only this first shock front fit reasonably well with the results from cases 1-7. Therefore, despite the irregular nature of the overpressure versus time curve near the shock front, cases 8 and 9 were finally treated in the same manner as the other cases, with the overpressure step at the first shock front being considered the critical factor.

For the case 9 calculations with valve opening times of 20 and 30 milliseconds, the shock front rise time was a little greater than the required 0.5 milliseconds. However, previous experience indicates that the parameters of interest are not very sensitive to this factor, and the high calculation cost prohibited repeating these calculations with smaller step sizes to obtain the required rise time.

The results of these valve opening time studies are summarized in Figures 101-103, which indicate the magnitude of the shock overpressure step versus valve opening time for each of the 9 cases studied.

Interpolation of these curves gives the maximum allowable valve opening time for each case, listed in Table 2 and graphed versus driver pressure to ambient pressure ratio in Figure 104. This curve does show a general trend, but it is not smooth. This lack of smoothness is at least partly attributed to the fact that the maximum allowable valve opening time is not a function of pressure ratio alone; it also depends on the temperature ratio, which is not a perfectly smooth function of the pressure ratio (see Figure 105) for the cases considered here.

4. CONCLUSIONS

The calculations done here indicate that the maximum allowable valve opening time is about 63 milliseconds for case 1, and somewhat less for the other, lower-pressure cases, as indicated in Table 2. The results for cases 1-7 are believed to be realistic; the results for cases 8 and 9 must be regarded with some skepticism. More reliable results would require a multidimensional computer model that is somewhat more complicated and substantially more expensive to run than the model used in this work.

USER EVALUATION SHEET/CHANGE OF ADDRESS

This Laboratory undertakes a continuing effort to improve the quality of the reports it publishes. Your comments/answers to the items/questions below will aid us in our efforts.

1. BRL Report Number _____ Date of Report _____

2. Date Report Received _____

3. Does this report satisfy a need? (Comment on purpose, related project, or other area of interest for which the report will be used.)

4. How specifically, is the report being used? (Information source, design data, procedure, source of ideas, etc.)

5. Has the information in this report led to any quantitative savings as far as man-hours or dollars saved, operating costs avoided or efficiencies achieved, etc? If so, please elaborate.

6. General Comments. What do you think should be changed to improve future reports? (Indicate changes to organization, technical content, format, etc.)

Name _____

CURRENT Organization _____

ADDRESS Address _____

City, State, Zip _____

7. If indicating a Change of Address or Address Correction, please provide the New or Correct Address in Block 6 above and the Old or Incorrect address below.

Name _____

OLD Organization _____

ADDRESS Address _____

City, State, Zip _____
